Debris-flow volume quantile prediction

from catchment morphometry

ABSTRACT

Estimation of the volumes of potential future debris flows is key for hazard assessment and mitigation. Worldwide, however, there are few catchments for which detailed volume-frequency information is available. We (1) reconstruct volume-frequency curves for 10 debris-flow catchments in Saline Valley, California, USA, from a large number of well-preserved, unmodified surficial flow deposits, and (2) assess the correlations between lobe-volume quantiles and a set of morphometric catchment characteristics. We find statistically significant correlations between lobe-volume quantiles, including median and maximum, and catchment relief, length (planimetric distance from the fan apex to the most distant point along the watershed boundary), perimeter, and Melton ratio (relief divided by the square root of catchment area). These findings show that it may be possible to roughly estimate debris-flow lobe-volume quantiles from basic catchment characteristics that can be obtained from globally available elevation data. This may assist design-volume estimation in debris-flow catchments where past flow volumes are otherwise unknown.

23

24 INTRODUCTION

25 Debris flows are dense masses of sediment and water that are common in mountainous
26 terrain, and that create low-gradient ($<15^\circ$) sediment fans through repeated deposition over time.
27 Such debris-flow fans are preferred locations for development in many mountainous regions
28 (Jakob, 2005). Estimation of both past and potential future flow volumes on fan surfaces is
29 critical for assessment of flow hazard and design of mitigation measures, because flow volume is
30 a prime control on flow velocity, peak discharge, and inundation area (e.g., Iverson et al., 1998;
31 Rickenmann, 1999; Griswold and Iverson, 2008). A global analysis of debris-flow hazards
32 between 1950 and 2011 shows that the number of fatalities increases exponentially with flow
33 volume (Dowling and Santi, 2014). Ideally, we should know the full flow volume-frequency
34 distribution, because maximum volumes are relevant for hazard assessment while median
35 volumes are relevant for sediment budget estimation (Bovis and Jakob, 1999).

36 Worldwide, however, there are very few catchments for which detailed volume-
37 frequency information is available (e.g., Jakob and Friele, 2010; Bennett et al., 2014). The
38 debris-flow volume reaching a fan depends on the amount of sediment available and the potential
39 of the flow to mobilize and transport this sediment, and is thus a function of catchment
40 morphometry, morphology, and geology as well as hydroclimatic conditions (e.g., Hungr et al.,
41 1984; Bovis and Jakob, 1999). In most systems, debris rather than water availability is the
42 dominant control on flow volume (e.g., Jakob and Bovis, 1996; Bovis and Jakob, 1999). Many
43 researchers have therefore attempted to correlate debris-flow volume with morphometric
44 catchment characteristics, predominantly catchment area and slope and channel length (e.g.,
45 Hungr et al., 1984; Jakob and Bovis, 1996; Marchi and D'Agostino, 2004; Ma et al., 2013). A

major shortcoming of these correlations is that they are based on only one to a few debris flows per catchment, inhibiting estimation of key flow-volume quantiles such as the median and maximum. It has been difficult to overcome this issue because of both the brevity of observational records relative to typical debris-flow return periods and the difficulty of determining flow volume directly, even in well-instrumented catchments with frequent flows (Schürch et al., 2011).

Fan surfaces are a potential archive of volume information for a large number of flows (e.g., Jakob et al., 2016). Debris flows deposit sediment levees and lobes (e.g., Blair and McPherson, 2009) whose dimensions may scale with the volume or peak discharge of the flow (Berti and Simoni, 2007). Unfortunately, debris-flow deposits are often reworked by post-depositional sediment transport processes or buried by subsequent flows, both of which obscure the original deposit dimensions and hinder volume estimation (e.g., Jakob and Bovis, 1996; Blair & McPherson, 2009; De Haas et al., 2014). In addition, large debris flows tend to spread out to form multiple lobe deposits, making it difficult to reconstruct the entire flow volume – especially if parts of the deposit are later reworked. As a result, the links between fan deposits, flow-volume quantiles, and the potential controls on flow volumes have not yet been comprehensively explored.

Here, we use the surfaces of 10 remarkably well-preserved debris-flow fans in Saline Valley, southwestern USA, which host numerous unmodified flow deposits, to: (1) create lobe volume-frequency curves from hundreds of well-preserved surficial debris-flow deposits; and (2) use these to assess the correlation between lobe-volume quantiles and a set of morphometric catchment characteristics, in order to explore and develop a method for debris-flow design volume estimation.

69

70 **STUDY AREA**

71 Saline Valley is a closed extensional basin located at the boundary between the Mojave
72 and Great Basin deserts in southeastern California, USA (Fig. 1). The southern and western
73 valley margins host a series of well-exposed debris-flow fans that have developed in response to
74 accommodation generation by slip on the Hunter Mountain and Saline Valley faults (Oswald and
75 Wesnousky, 2002). We focus on 10 of those fans whose surfaces preserve abundant debris-flow
76 deposits with clear primary flow features and negligible secondary modification.

77 Eight fans, S01-08, originate from the Nelson Range in the southern part of the valley
78 (Fig. 1). The Nelson Range is underlain by the Early Jurassic Hunter Mountain quartz monzonite
79 batholith (Oswald and Wesnousky, 2002). Fan S03 is fed by two subcatchments, each of which
80 contributes sediment to a separate part of the fan surface. We treat those two subcatchments and
81 their corresponding fan surfaces as individual systems in the analyses presented here.

82 A ninth debris-flow fan, N01, originates from the Inyo Mountains in the northern part of
83 Saline Valley (Fig. 1). The catchment of this fan consists mostly of Paleozoic marble, quartzite,
84 and chert with a small area of quartz monzonite in the catchment headwaters (Conrad and
85 McKee, 1985).

86 Saline Valley is located in the rain shadow of the Sierra Nevada and Inyo Mountain
87 ranges to the west, with mean annual precipitation of 100-200 mm (PRISM, 2015). Historical
88 records in nearby Owens Valley show that recent debris flows in the region have been
89 predominantly triggered by high-intensity summer rainstorms (e.g., Beaty, 1963; Blair and
90 McPherson, 1998).

91

DATA COLLECTION AND ANALYSIS

We estimated debris-flow lobe volumes from a gridded LiDAR dataset with 0.5 m horizontal cell size (Suppl. Fig. 1), collected in April 2007 by the National Center for Airborne Laser Mapping (NCALM). Debris-flow lobe deposits were manually identified and mapped using hillshade, curvature, and local slope maps (cf. Staley et al., 2006; Roering et al., 2013), cross-checked by field measurements in September 2017 (Suppl. Fig. 2). Lobe thickness h [m] was measured by defining the maximum thickness of a lobe extracted from elevation cross- and long-profiles, assuming a planar bed underneath the lobe deposits (Suppl. Fig. 1). Lobe width w [m] was defined as the maximum width of the lobe deposit. The cross-sectional area of each debris-flow lobe A_l [m²] was then calculated by assuming a trapezoidal cross-section (cf. De Haas et al., 2015):

$$A_l = 0.75 h w \quad \text{Eq. 1}$$

We assumed a conservative uncertainty on A_l of 50%, accounting for variation between triangular and rectangular cross-sections and deviations from a planar bed. Iverson et al. (1999) and Griswold and Iverson (2008) showed that the cross-sectional area of a debris flow is a semi-empirical function of its total volume V [m³]:

$$A_l = \varepsilon V^{2/3} \quad \text{Eq. 2}$$

Based on 15 recent non-buried debris flows we find $\varepsilon \approx 0.1$ for the Saline Valley fans ($R^2 = 0.82$; Suppl. Fig. 3), similar to the ε found by Griswold and Iverson (2008) for 50 non-volcanic debris flows worldwide. The estimated debris-flow volumes are accurate within a factor 2 (Suppl. Fig. 3). For our calculation we assume $\varepsilon = 0.1 \pm 0.025$. We used eq. 2 to convert the measured cross-sectional areas to total lobe volumes, propagating the errors in A_l and ε .

Direct measurement of total flow volumes is generally not possible for all but the most recent flows due to burial by more recent deposits. For the same reason, we typically cannot identify whether individual flows deposited one or multiple lobes. Note that the volume of the largest debris flows, which are most likely to have formed multiple lobes, may thus have been underestimated (e.g., Blair and McPherson, 1998; De Haas et al., 2016; 2018).

We compared the inferred debris-flow lobe volumes to a wide range of morphometric catchment characteristics (Table 1). The LiDAR dataset does not cover the full fan catchments, and therefore we used ASTER Global Digital Elevation Model (GDEM) data to infer these catchment characteristics. This elevation data set is globally available and has a 30 m horizontal resolution, ensuring worldwide applicability but limiting our analysis to simple catchment characteristics. We assessed the correlations between catchment characteristics and the 25, 50, 75, and 99 percentiles and maximum lobe-volume quantiles through linear regression.

RESULTS

The number of individual debris-flow lobe deposits identified on the fans ranges from 84 on fan S03b to 851 on fan S06 (Fig. 2). The smallest reconstructed median debris-flow lobe volume, $140 \pm 55 \text{ m}^3$, was found on fan S03b. The largest median lobe volume, $830 \pm 330 \text{ m}^3$, was found on fan S04. The reconstructed maximum lobe volumes range from $4400 \pm 1750 \text{ m}^3$ on fan S02 to $92000 \pm 37000 \text{ m}^3$ on fan S07. The volume distribution curves highlight that the lobe volumes on a single fan can vary by four orders of magnitude.

Overall, median lobe volume is the quantile that shows the best correlation with catchment characteristics (Fig. 3). There are statistically significant correlations ($p < 0.05$) between median lobe volume and catchment area, relief, length, perimeter, and Melton ratio

(Suppl. Tab. 1). The goodness-of-fit (R^2) of these correlations ranges between 0.39 and 0.51, where Melton ratio performs best. There are also statistically significant relations between maximum lobe volume and catchment relief, length, and perimeter, while the relation with Melton ratio is close to significant with a p-value of 0.07. Catchment perimeter, length, relief and Melton ratio generally show statistically significant correlations with most other lobe-volume quantiles, and where correlations are statistically insignificant the p-values are nonetheless still typically smaller than 0.1.

We find no statistically significant correlations and poor goodness-of-fit values, generally below 0.20, between lobe-volume quantiles and mean catchment slope, relief ratio, form factor, elongation ratio, and circularity index (Suppl. Tab. 1).

Our dataset shows two outliers in the relationships between lobe volume and catchment area, relief, Melton ratio, perimeter and length, corresponding to the two smallest watersheds, S02 and S03b (Fig. 3). These outliers have relatively small lobes, which for maximum volume are almost one order of magnitude lower than would be expected based on the correlations with catchment characteristics.

Based on our very limited sampling, differences in catchment lithology do not seem to affect the lobe volume-catchment characteristic relationships in our dataset. The flow volumes on fan N01, with a catchment that consists predominantly of metasedimentary rock, follow similar relationships with catchment characteristics as those fed from the quartz monzonite catchments (Fig. 3).

DISCUSSION

Our results show that, at least in climatically- and tectonically-similar areas, it may be possible to predict debris-flow lobe-volume quantiles, including median and maximum, based on catchment relief, perimeter, length, area and Melton ratio. These findings may assist in debris-flow hazard assessment and mitigation where data on lobe or flow volumes are otherwise unknown, which holds true for the vast majority of catchments. Moreover, our findings may help to estimate sediment budgets where such data are otherwise unavailable (Bovis and Jakob, 1999). Although our data do not show how climatic and lithological conditions may affect lobe-volume quantiles, we suggest that, where the flow-volume distribution of a debris-flow system is known, flow volume quantiles in neighboring catchments may be reasonably estimated based on a catchment relief, perimeter, length, area or Melton-ratio correction.

A number of studies have used catchment characteristics to discriminate between the likely predominance of debris-flow and streamflow sediment transport. In particular, catchment area (e.g., de Scally and Owens, 2004), length (e.g., Wilford et al., 2004), and Melton ratio (e.g., Bertrand et al., 2013) have demonstrated skill in discriminating the formative fan process. Not surprisingly, these are the same catchment characteristics as those found here to be capable of predicting debris-flow lobe-volume quantiles.

So why do these catchment characteristics determine process and lobe volume? Debris-flow volume is a function of two elements: (1) the volume of the initiating failure or failures, and (2) the volume changes, by entrainment and deposition, along the transport path (Jakob, 2005). In the simplest case, debris flows may initiate on the steep slopes of the upper catchment, after which they can grow in volume by eroding sediment while traversing through the catchment to finally deposit on the fan. As such, for a given initial failure volume, the flow volume entering a fan depends on the erosional potential of the debris flow and the amount of material available for

182 entrainment (e.g., Jakob et al., 2005). The entrainment rate at the base of a debris flow likely
183 increases with bed slope (e.g., Iverson & Ouyang, 2015), and therefore flow volume is likely to
184 increase with catchment relief (Fig. 3). Similarly, the larger the distance a debris flow traverses
185 through steep channels in a catchment, the larger the potential for net entrainment (assuming that
186 sufficient bed sediment exists and that its density and saturation are sufficient to promote
187 entrainment; Iverson, 2012), and the larger the flow volume may become. This may explain the
188 increasing flow-volume quantiles with catchment area, perimeter and length (Fig. 3). One should
189 note, however, that these effects are partly damped because the average catchment gradient
190 decreases with catchment area. Similarly, catchment length, perimeter and relief are strongly
191 related and increase logarithmically with basin area and the square-root of catchment area scales
192 linearly with basin relief, which defines the Melton ratio ($R^2 > 0.9$; Suppl. Fig. 4).

193 It is important to remember that our estimated volumes are based on the cross-sectional areas
194 of individual lobes, and will therefore underestimate the volume of large flows that form
195 multiple depositional lobes (e.g., Beaty, 1963; Blair and McPherson, 1998; 2009). Volume
196 estimates for flows forming multiple lobes, however, are only possible by direct measurement or
197 for the most recent events on a fan surface which have not been buried by subsequent flows. As
198 such, it is currently not possible to obtain large datasets of debris-flow volumes corrected for
199 multiple lobe formation. It is important to realize, however, that for some hazard applications
200 (such as damage to infrastructure) it is volume of sediment deposited at a point, rather than the
201 total flow volume that is most relevant. Our approach describes the probability to find a lobe of a
202 given size on a debris-flow fan, but for hazard assessment and mitigation it is also important to
203 understand the frequency of such flows. To advance the novel catchment-morphometry based
204 method to estimate debris-flow quantiles presented here, future research should thus focus on

direct estimation of flow volume-frequency distributions from a number of debris-flow catchments in diverse climatic and lithological settings.

CONCLUSIONS

We have reconstructed debris-flow lobe-volume distributions from a large number of well-preserved flow deposits on 10 fans in Saline Valley, California, USA, and compared lobe-volume quantiles to a set of morphometric catchment characteristics. Our results show that, when controlled for climatic and tectonic setting, lobe-volume quantiles, including 25, 50, and 75 percentiles and the maximum, depend on catchment area, length, perimeter, relief, and Melton ratio. This implies that simple catchment characteristics, which can be extracted from globally-available elevation datasets, may be used to obtain rough estimates of minimum flow design volumes for sediment budgets as well as for hazard assessment and mitigation. While these relationships are promising, future research should focus on the generation of flow volume-frequency distributions from different climatic and lithological settings worldwide against which to test the wider application of these estimates.
